Central giant cell granuloma in anterior maxilla

Shwetang Goswami¹, Haripriya², Yashwanth Yadav³, Ram Mohan⁴

ABSTRACT:
Giant cell granuloma is an uncommon bony lesion in the head and neck region, most commonly affecting the maxilla and mandible. Although it is a benign disease process, it can also be locally destructive. Surgery is the traditional and still the most accepted treatment for giant cell granuloma. The case described here involved the anterior maxilla.

Key words: central giant cell granuloma, maxilla, residual cyst.

CASE REPORT

A 28 year old female patient reported to the department of oral and maxillofacial surgery with a chief complaint of pain and swelling in the upper jaw. The swelling was painless and gradually increasing in size. On clinical examination, a firm, non-pulsatile swelling was noted in the anterior maxilla. The lesion was not tender on palpation and there was no evidence of sinus tract or area of fistula. The patient had no history of trauma or recent tooth extraction. The lesion was not associated with any symptoms like numbness or paresthesia.

The patient underwent a thorough dental and medical history. She was a non-smoker and non-alcoholic. She had no history of any systemic disease. Her medical and dental records were reviewed for any history of trauma or recent tooth extraction. She was a non-smoker and non-alcoholic.

Radiographically, an ostoid trabeculated radiolucency was noted in the anterior maxilla. The incisors were displaced laterally. There was no evidence of any sinus tract or area of fistula. The lesion was not associated with any symptoms like numbness or paresthesia.

The patient underwent a biopsy of the lesion. The histopathological examination revealed the typical features of a central giant cell granuloma. The bone was destroyed and replaced by a proliferation of giant cells. The patient was treated with surgical excision of the lesion.

Giant cell granulomas are benign lesions that are often treated with surgical excision. They can occur in any bone, but are most commonly seen in the maxilla and mandible. They are typically asymptomatic, but can cause pain or swelling. The lesion can be solitary or multiple.

In conclusion, the case reported here was a typical example of a central giant cell granuloma in the anterior maxilla. The patient was treated successfully with surgical excision of the lesion. The lesion was not associated with any symptoms like numbness or paresthesia. The patient was followed up regularly and there was no evidence of recurrence.

front teeth region since two months. Patient gave a history of trauma 2 months back. Later the patient developed a swelling in the same region and got her upper front teeth extracted along with pus drainage. One month later patient developed swelling again which increased in size gradually.

On clinical examination, a single diffuse swelling was seen measuring approximately 2x3 cm extending from midline of upper lip and philtrum to left nasal ala obliterating the naolabial fold on left side (Figure 1). On intraoral examination, 21, 22 are missing. A single well defined swelling measuring 2x3 cm approximately was seen extending from 11 to 23; involving marginal, papillary and attached gingiva and extending palatally (Figure 2). On palpation, the swelling was soft and tender. A clinical diagnosis of radicular cyst or residual cyst or aneurysmal bone cyst, pyogenic granuloma, gingival fibroma was made.

An orthopantamograph (OPG) and occlusal radiograph were taken where OPG showed a radiolucent region extending from 21 to 23 (Figure 3). Computed tomography scan (CT) showed the mass extending inferiorly into the body of the maxilla up to alveolus (Figure 4). Medially, it crossed the midline of the maxilla, distally it extended up to 23 and superiorly it extended up to the pyriform aperture, suggesting complete involvement of the anterior maxilla. Two separate histopathological examinations confirmed Central Giant Cell Granuloma. A provisional diagnosis of radicular cyst, residual cyst or aneurysmal bone cyst, pyogenic granuloma, gingival fibroma was made.

An incisional biopsy was performed and specimen was sent for histopathologic examination (Figure 5). The H and E stained sections show presence of numerous multinucleated giant cells in a back ground of cellular stroma composed of round to spindle shaped cells. These multinucleated giant cells were dispersed uniformly throughout the connective tissue stroma, suggestive of central giant cell granuloma. Hence a final diagnosis of central giant cell granuloma was made.

Discussion:

GCG has been defined by the World Health Organization as an intra-osseous lesion consisting of cellular fibrous tissue that contains multiple foci of hemorrhage, aggregations of multinucleated giant cells, and, occasionally, trabeculae of woven bone. GCG accounts for <7% of all benign lesions of the mandible and maxilla in tooth-bearing areas. The mandible, anterior to the first molar teeth, is the most commonly affected site. Central GCG (e.g., GCG of the mandible and maxilla) is less common than peripheral GCG of the extremities. GCG affects children and adults, and may occur at any age, but is most commonly seen in the first 3 decades. It is more frequent in females than in males. The etiology of the GCG still remains to be defined. It has been reported that the origin of this lesion could be triggered by trauma or inflammation. The common effects of GCG are: painless swelling that remains undetected until facial asymmetry, impaired nasal breathing, and loosening or displacement of teeth. Localized swelling is an important clinical feature. The swelling is smooth, and palpation can reveal a rubbery, elastic sensation where the bone has thinned. Although the lesion is expansile and invasive, it does not usually involve the perineural sheets. For this reason, paresthesia is not usually observed in these patients.

The clinical behavior of GCG ranges from a slowly growing asymptomatic swelling to an aggressive lesion. When GCG is a slow-growing lesion, it can be asymptomatic and discovered on a routine X-ray, while the rapidly expanding, aggressive variety is characterized by pain and facial swelling. These fast growing lesions also have a high rate of recurrence. It has been reported that recurrence is usually found when the lesion perforates the cortical plates to involve the surrounding soft tissue. There have been reports of recurrence as early as 3 years and as late as 22 years.

Radiologic features vary from undefined destructive lesions to a well-defined, multilocular appearance. Teeth or roots displacement are the most consistent features which are well appreciated on CT than on plain film. However none of these radiological features is specific for GCG. It is important to bear in mind that the X-ray appearance of the lesion is not pathognomonic and may be confused with many other lesions of the maxilla and the mandible.

Histologically, multinucleated giant cells, in a cellular vascular stroma, and often new bone formations are detected. The osteoclast-like giant cells have a patchy distribution and are usually associated with areas of haemorrhage.

Ultrastructurally, the proliferating cells include spindle-shaped fibroblasts, myofibroblasts, and inflammatory mononuclear cells. GCG is a vascularized lesion that shares many features with the aneurysmal bone cyst. Differentiation from the latter can also be difficult histologically. However, the aneurysmal bone cyst is characterized by a lining of flat non-endothelial cells. Brown tumour of hyperparathyroidism is histologically very similar to GCG. Thus, all patients with suspected GCG should have serum calcium, phosphate and alkaline phosphatase levels evaluated, to exclude the possibility of hyperparathyroidism. The non-ossifying fibroma is histologically very similar to the GCG which can, however, be differentiated from the latter since the granuloma-like aggregate of giant cells and the fibrous stroma found in GCG, are not typical features of non-ossifying fibroma.

Treatment of GCG of the maxilla and mandible with calcitonin has also been reported. GCGs have been successfully treated with calcitonin, in various concentrations, for at least 1 year, and complete remission of GCG has been observed, without signs of recurrence. However, calcitonin therapy can be complicated by side-effects, such as hypocalcaemia and secondary hyperparathyroidism. Furthermore the relatively long duration of treatment can be more intolerable, for some patients, especially children. Another form of treatment for GCG consists in weekly intra-lesional injections with corticosteroids, successful results have been reported in the literature. Steroid treatment was first suggested by Body et al., in 1981. Corticosteroid treatment is, however, relatively contraindicated in certain medical conditions, such as diabetes mellitus, peptic ulcer, and generalized immuno-compromised states. Non-surgical therapies for GCG are probably good treatment options for small slow-growing lesions, while successful treatment of painful, large, and rapidly growing lesions is still more likely to be achieved by surgical removal.

Conclusion:

GCG is a relatively rare entity of benign histologic nature but can have a very aggressive local behavior. A definitive diagnosis is reached by biopsy of the lesion. It should be present in the differential diagnosis in all expansive osteolytic lesions affecting the jaw or maxilla, such as pyogenic granuloma, gingival fibroma, fibrosarcoma and distant metastases of tumors. Its treatment includes from removal of it to the simple intralesional injection of corticosteroids or the use of calcitonin or INF-α, always with clinical and radiological control due to its high rate of recurrence. Given the failure of conservative treatment, management be should an aggressive resection and reconstruction, when it is possible.
